Study Objectives: Maxillomandibular advancement surgery is a well-supported treatment option for obstructive sleep apnea in patients who have not responded to or who have not tolerated nonsurgical management. The usual straightforward surgical procedure can be made much more difficult with numerous impacted supernumerary teeth, as is frequently seen in patients with cleidocranial dysostosis.

Methods: The preoperative planning, surgical procedure, and postoperative phase of the maxillomandibular advancement surgery for a 51-year-old patient with severe OSA (apnea-hypopnea index 94 events/h in 2010) and concomitant cleidocranial dysostosis will be discussed in this case report.

Results: When compared to the preoperative polysomnographic examination, striking improvements were noted on the examination at 8 months after surgery (apnea-hypopnea index from 94 to 21 events/h).

Conclusions: The results of this case showed that using traditional maxillomandibular advancement surgical protocols, despite the numerous impacted supernumerary teeth, provides excellent results for the treatment of severe OSA. The patient will require further follow-up and likely subsequent treatment of his remaining dentition.

37.9. He was, at that time, enrolled in a weight loss program. He presented with a flat profile, frontal bossing, and sunken nasal bridge. He had some degree of hearing loss bilaterally, present since birth. He had no nasal or sinus complaints, no soft palate, tonsillar, or tongue base hypertrophy though he did present with a Mallampati III airway with a maximum incisal opening of approximately 28 mm (Figures 1 and 2). He had multiple palpable and multiple non-palpable impacted teeth. The only erupted teeth present intraorally were teeth numbers 4, 5, 12, 21, 28, and primary teeth C, F, H, M, N, O, P, Q, R therefore there was no measurable occlusion (Figure 3).

A panoramic radiograph (Figure 4) revealed fully impacted teeth #1, 2, 6, 7, 8, 9, 10, 11, 15, 16, 17, 18, 19, 22, 23, 24, 25, 26, 27, and 32. The ascending ramus are slightly narrow and the coronoid processes thin and pointed.

Lateral cephalogram (Figure 5) revealed a hypoplastic maxilla and mandible, and an obtuse mandibular plane angle (76.3 degrees, normal 65). Relative airway restriction in the anterior and posterior dimension is also visualized. Computed tomography (CT) scan obtained while the patient was entirely conscious, revealed narrowed upper airway space as well (Figure 6).

Due to the occlusal findings, the traditional orthognathic acrylic splint fabrication was difficult. Using the 14 teeth that were erupted with only 4 actually in occlusion, both the interim and final acrylic splints were made using these contacts as well as full contact with the attached gingival overly both the upper and lower alveolus. With so few erupted teeth, both preoperative orthodontics and intraoperative archbars were not possible for stabilization of the splints and the arches in their new position. Thus, intermaxillary fixation screws were planned for intraoperative stabilization.

Surgical treatment was performed under general anesthesia using a nasal endotracheal tube. Intermaxillary screws were placed first; 4 in the maxilla and 4 in the mandible, all 8 mm in length. The traditional horizontal incision and osteotomy were performed at the LeFort 1 level. As per usual surgical protocol, a double guarded nasal osteotome was used to separate the nasal
septum from the nasal crest of the maxilla. The single guarded osteotome was then used to separate the lateral nasal wall/medial maxillary sinus wall. A small, then large, curved osteotome was used to separate the maxilla from the pterygoid plates, and a Rowe disimpaction forceps was used to disimpact that maxilla. Given the location of the multiple supernumerary teeth, many were included in the osteotomy and left in place. The interim acrylic splint was placed into the mouth and wired in place using the intermaxillary fixation wires. After adjusting and enlarging the piriform aperture, the maxilla was held up and into the final planned position, 10 millimeters anterior to the preoperative position, and secured with 4 L-shaped mini plates and 16 six-millimeter screws. The interim splint was removed and the maxilla was found to be stable in the new position.

The surgery was continued with bilateral sagittal split osteotomy of the mandible. Once again, the tradition approach and osteotomies were used. A proper split was obtained bilaterally and both the inferior alveolar nerve and full bony impacted teeth #17 and 32 were visualized and free of trauma. Given the highly impacted nature of these impacted teeth and the expected subsequent weakening of the mandible, they were left in place. After the final acrylic splint was placed and intermaxillary fixation was complete, the mandible was advanced 10 millimeters and fixated in place using 3 bicortical screws on the superior aspect of the mandible placed transcutaneously using a trocar. The intermaxillary fixation wires and intermaxillary fixation screws were removed in totality. The patient was advised to follow a liquid diet protocol during the 5 weeks postoperatively then was to resume normal diet.

The patient reported feeling more rested with less daytime somnolence within the first week postoperatively. He continued to improve over the first several weeks and transitioned easily from full liquid diet to solids as instructed. He reported easily working 12-hour shifts without the fatigue he used to feel prior to surgery. His mood was elevated and his outlook on life more positive. Clinically he appeared to be well-healed from a surgical standpoint, with no mobility of the segments, no mucosal dehiscence, no signs or symptoms of active infection. His postoperative radiographs revealed stable hardware and no acute or chronic complications of the teeth in the line of osteotomy (Figures 7–12).

On follow-up polysomnogram, done December 2013, the AHI dropped down to 21 episodes per hour of sleep, with only 3 minutes 45 seconds with an oxygen saturation below 90%, and a total sleep time (TST) of 394 minutes (Table 1).

**DISCUSSION**

It is well documented in the literature that maxillomandibular advancement (MMA) surgery increases anterior-posterior and medial-lateral airway size, which can help improve or eliminate OSA. In 2013, Sittitavornwong et al. demonstrated that, independent of age or gender, all patients who underwent MMA, showed an increase in airway cross-sectional area and a decrease in the pressure effort at every airway level after MMA. In general, as the airway obstruction worsens, a greater pressure effort is required to inspire a normal volume of air. Increasing the 3-dimensional airway space, should decrease this pressure effort, thus decreasing the work of breathing. By changing the skeletal framework, MMA increases the pharyngeal space, pulling the tongue and suprahoid muscles...

There is a significant evidence that early treatment of the dental signs of cleidocranial dysostosis, including multiple supernumerary teeth, malformed dentition, and failure of eruption of teeth, is beneficial to both the aesthetics and long-term functionality of patients. Extraction of supernumerary teeth, exposure of impacted teeth with traction and orthodontics can lead to a stable long-term occlusion when patients are treated in the pubescent and early teen years.

A direct cause and effect link between cleidocranial dysostosis and obstructive sleep apnea has never been established. It does not seem that OSAS is one of the clinical manifestations of the syndrome. Age, gender, and certainly obesity are all well documented to be correlated with OSA. The prevalence of moderate or severe OSA in the elderly has been reported in the 7% to 44% range, with a much lower influence from BMI/obesity. In the Caucasian population, the cutoff value of BMI for obesity is 30 kg/m², and has been reported as low as 23 kg/m² in some Asian-Indian populations. With the aging population and increasing obesity prevalence, we will certainly see an overall increase in OSAS, including patients born with cleidocranial dysostosis. In patients with cleidocranial dysostosis that have been treated with early intervention for the supernumerary, malformed, and impacted teeth, the traditional maxillomandibular advancement surgery approach would be simple to apply. In those patients that have no previously been treated and present with many unerupted teeth and without a stable occlusion, the surgical planning can be complicated. As seen in this case report, maxillomandibular advancement surgery via the conventional approach, leaving the unerupted teeth within the osteotomy sites both during downfracture/sagittal split and during fixation, can be effective in treating and improving severe OSA.

CONCLUSION

In the setting of severe obstructive sleep apnea, cleidocranial dysostosis is not a contraindication for maxillomandibular advancement surgery, even with the presence of multiple impacted and missing teeth.
